Abstract. A new geomagnetic parameter was suggested twenty years ago by Y. Galperin, the Galperin $L$ parameter, and it was introduced into the CNES Maglib for French-Russian projects in the exploration of the distant magnetosphere. The definition and the advantages of the Galperin $L$ parameter are recalled in this brief paper. Unforeseen possibilities in the use of this parameter for mathematical models of the magnetosphere are stressed using past results obtained with the Mead model. The Galperin $L$ parameter is shown to add, in the synchronous region, a quantitative capability to the qualitative description (labelling) of the magnetosphere. More work will be necessary to adapt past mathematical models to present numerical models and extend the domain of the quantitative applications of the Galperin $L$ parameter.

Keywords. Magnetospheric physics (Magnetospheric configuration and dynamics, General or miscellaneous)

1 Introduction

Corrected geomagnetic coordinates were introduced in the 1950s to better organize data in the high-latitude regions. Hultquist (1958a) calculated the spherical harmonic coefficients of the internal magnetic field of the Earth in a centered dipole coordinate system. In a later work, Hultquist (1958b) calculated the deviations of the real field line from the dipole field line due to the perturbation of the higher spherical harmonic coefficients. The integrated deviations along the dipole field line gave the displacement vectors in the Northern and Southern hemispheres. The corrected geomagnetic coordinates of a point were the dipole geomagnetic coordinates corrected by the displacement vector. Hakura (1965) improved the method by tracing the field line down to the geomagnetic equator using an IGRF magnetic field. From this location a dipole field line was traced back to the Earth, giving the corrected geomagnetic location of the point. More recently, Stasiewicz (1991) extended Hakura’s solution by combining internal and external fields. From a point in space the tracing down to the Earth is performed using the total magnetic field (IGRF + the Kosik 1998 or Tsyganenko 1989 models), then from this conjugate point on Earth, the field line tracing down to the geomagnetic dipole equator uses the internal magnetic field only. These efforts presumably led Y. Galperin to introduce for the high altitude and high inclination magnetospheric spacecraft a modern shell parameter in replacement of the McIlwain $L$ parameter. This parameter was introduced in the CNES Maglib. The Maglib software includes routines for the calculation of the internal magnetic fields, external magnetic fields, transformation matrices between different frames of reference and the calculation of geophysical parameters.

The Maglib was developed for the treatment of data from the Interball and Cluster spacecraft (Hapgood et al., 2004). At the same time, Prokhorenko (1995) introduced this parameter at IKI (Cosmic Research Institute, Moscow), for the French-Russian planning of the Interball experiments. In this short paper we recall the definition of the Galperin $L$ parameter and its ability to label fluxes in the outer magnetosphere. We show that this parameter has a major advantage over the choice of an equatorial labelling, as we demonstrate its direct link with past results obtained with a simplified mathematical model of the magnetosphere in the synchronous region. The Galperin $L$ parameter also has a quantitative capability in this region.
2 The McIlwain L parameter

Northrop and Teller (1960) have shown that the motion of charged particles could be described using adiabatic invariants. In the absence of perturbations the motion of the particles can be described by the first two invariants, \( \mu = E/B_m \) and \( J = 2 p I \), where \( E \) is the the energy of the particle, \( p \) the momentum and \( B_m \) the magnetic field intensity at the mirror point. \( I \) is the path integral between the mirror points \( M, M' \):

\[
I = \oint_{M'M} \sqrt{1 - \frac{B}{B_m}} \, ds. \tag{1}
\]

The points in space that have the same value of \( B_m \) and \( I \) form a ring in each hemisphere and a particle bouncing between the mirror points will drift along a shell described by the field lines that connect these rings. In a dipole field particles that have different mirror points on the same field line will drift in longitude to the same field line. In the Earth’s heterogeneous magnetic field this will not be the case and two particles that have two different mirror points along the same field line of force will drift in longitude to different lines of force. But this effect is relatively small, as was discussed in detail by Roederer (1970).

Taking into account the properties of the dipole magnetic field, McIlwain (1961) introduced a smoothing parameter \( L \), defined for a point in the Earth’s magnetic field by the equation:

\[
L^3 B_m / M = F \left( I^3 B_m / M \right), \tag{2}
\]

where \( M \) is the dipole moment of the Earth. McIlwain presented the function \( F \) in a table of 125 values and as a set of polynomials of the form

\[
L_n \left( L^3 B_m / M - 1 \right) = \sum_{n=0}^{6} c_n \left( L^3 B_m / M \right)^n \tag{3}
\]

where \( I \) and \( B_m \) are to be calculated with a representation of the Earth’s field. The \( BL \) coordinate system is perfectly adequate for the inner magnetosphere (equatorial distance less than 4 Re).

3 The Galperin L parameter

For the outer magnetosphere, shell splitting from external magnetic sources is more and more important with the increase in the distance to the Earth. The shell splitting due to the multipoles of the magnetic field of the Earth can be neglected with respect to this outer zone shell splitting. The McIlwain parameter is no longer an adequate parameter.

Roederer (1970) suggested other labelling techniques, using, for example, the third adiabatic invariant. Galperin suggested the following recipe for a new \( L \) parameter.

From the point \( s \) of the measurement

\[ \text{– trace the field line down to the Earth with the complete internal plus external magnetic field} \]

\[ \text{– for the conjugate point calculate the usual McIlwain \( L \) parameter using the internal field only.} \]

This technique is illustrated in Fig. 1. It can be applied even in the case of open field lines as the first step is the tracing down to the Earth.

In some sense, the Galperin \( L \) parameter can be considered as a geomagnetically corrected McIlwain \( L \) parameter.

4 The Galperin L parameter and the labelling of directional fluxes in the outer zone

If we consider a bunch of particles of very small pitch-angle measured in the equatorial plane along a distorted field line, this bunch of particles will follow the field line until it reaches the mirror point and then bounces back. The directional fluxes associated with these particles can be measured along the field line. If one uses the usual McIlwain \( L \) parameter which can be approximated in the outer zone to the dipole \( L \), the labelling of these directional fluxes can be obtained by tracing dipole field lines through the measurement locations. To each location a different dipole field line is associated, thus to the measurements of this bunch of particles are associated a series of dipole \( L \) values, and more precisely, a continuum of \( L \) values between \( L_{\min} \) and \( L_{\max} \). \( L_{\min} \) corresponds to the measurement at the equator and \( L_{\max} \) corresponds to the measurement at the mirror point.
If we now use the Galperin L method, we trace the real field line down to the Earth, i.e. we follow the bunch of particles along its bounce, then we trace a dipole field line (approximation of the internal field in the outer zone) from the Earth down to the equator and obtain the Galperin L parameter nearly equal to $L_{\text{max}}$. In this case all the measurements of this bunch of particles have the same label, L. In Fig. 2, the bunch of particles is represented as an arrow. The McIlwain parameter for each measurement along the real field line is obtained in this outer region of the magnetosphere by tracing a dipole field line through the point of measurement. We obtain a series of quasi-McIlwain L values between 5.2 and 7. The Galperin L parameter corresponds to the outermost dipole field line and has a value of 7. This value will be the same for all the measurements along the real field line.

5 The Galperin L parameter and its quantitative aspects

During the past 50 years, several mathematical models of the magnetosphere have been built, from the Mead model to the recent models Kosik (1998) or Tsyganenko (1989). For the sake of simplicity and for the ease of demonstration we will refer specifically to the results obtained using the Mead model.

Ignoring the higher order harmonics, Mead (1964) showed that the outer magnetosphere can be described with three potential terms:

$$V = \frac{1}{r^3} g_1^0 \cos \theta + r g_1^0 \cos \theta + \frac{\sqrt{3}}{2} r^2 g_2^1 \sin 2 \theta \cos \varphi. \quad (4)$$

In this expression, $r$, $\theta$, $\varphi$ are the spherical coordinates, $r$ is expressed in Earth radii, $\theta$ is the colatitude measured from the north magnetic axis, and $\varphi$ the longitude counted from the noon meridian. The first term is the dipole magnetic field ($g_1^0=0.31$ Gauss), the second term is an axisymmetric compression term ($g_1^0=0.00025$ gauss) and the third term is the noon-midnight asymmetry term ($g_2^1=-0.00012$ Gauss). The magnetic field components can be derived by taking the gradient $\vec{B} = -\nabla V$.

$$B_r = \frac{2}{r^3} g_1^0 \cos \theta - g_1^0 \cos \theta - \sqrt{3} r g_2^1 \sin 2 \theta \cos \varphi \quad (5a)$$

$$B_\theta = \frac{1}{r^2} g_1^0 \sin \theta + \sqrt{3} r g_2^1 \sin \theta - \sqrt{3} r g_2^1 \cos 2 \theta \cos \varphi \quad (5b)$$

$$B_\varphi = \sqrt{3} r g_2^1 \cos \theta \sin \varphi. \quad (5c)$$

Inspection of Eq. (5b) for $\theta=\pi/2$ shows that the second term $g_2^1$ is an axisymmetric field added to the dipole field, while the third term $g_2^1$ compresses the dipole field at noon and depresses the dipole field at midnight.

Fig. 2. Arrows represent the directional fluxes of a bunch of particles mirroring near the Earth. For the outer zone the McIlwain L can be approximated by the intersections of the dipole field lines with the equator. The directional fluxes have different McIlwain L parameters depending on the latitude. There is only one Galperin L parameter which corresponds to the distance of the intersection of the outermost dipole field line with the equator, a distance expressed in Earth radii.

It is possible to derive the field lines equations using a linearization technique, from which we obtain (Kosik, 1971a)

$$r = L \sin^2 \theta \left\{ 1 - \frac{1}{2} \frac{g_1^0}{g_1^0} L^3 \sin^6 \theta + \frac{3}{4} \left( \frac{g_1^0}{g_1^0} \right)^2 L^6 \sin^{12} \theta + \frac{2 \sqrt{3}}{7} \frac{g_1^1}{g_1^0} L^4 \left( \frac{\sin^4 \theta}{7} - \frac{\sin^9 \theta}{3} \right) \cos \phi_0 \right\} \quad (6a)$$

$$\phi = \phi_0 + \frac{\sqrt{3}}{7} L^4 \sin^7 \theta \sin \phi_0. \quad (6b)$$

Equation (6a) gives the radial position of a field line point of colatitude $\theta$, and the longitude $\phi$ is counted from the noon meridian. In this equation one recognizes a dipole term which corresponds to the magnetic field of the Earth. The other terms between the brackets represent the perturbation components of the dipole field line, i.e. a uniform compression component, and an asymmetric compression component. Equation (6b) gives the deviation of the field line from a meridian plane. Figure 3 shows a real field line and its associated dipole field line. A bunch of particles would follow the real field line, and the directional fluxes would
be labelled with the parameter $L$: the $L$ parameter of our real magnetic field line is clearly the Galperin $L$ parameter. There is a one-to-one correspondence between the Galperin $L$ parameter and the field line label.

The adiabatic invariants $I$ and $B_m$ can be expressed as a function of $L$, the mirror point colatitude $\theta_m$ and the longitude $\phi$. Taking into account the conservation of these invariants along a drift shell it is possible to express one variable as a function of the other two. This leads to the drift shell equation (Kosik, 1971a)

$$L = L_0 \left[ 1 + \frac{p_1^2}{g_1^0} L_0^4 p(\theta_m) (\cos \phi - \cos \phi_0) \right],$$

where $L$ is the Galperin $L$ parameter at longitude $\phi$ and $L_0$ is the Galperin $L$ parameter at longitude $\phi_0$. In this equation $p(\theta_m)$ is a function of the mirror point colatitude $\theta_m$ of the particle.

If a convection electric field with potential $V = A L \sin \varphi$ is taken into account, where $A$ is assumed to be a constant equal to $2.5 \text{ kV} / L$ in $L$ units, the drift shell equation is a little more complicated (Kosik, 1971b):

$$L = L_0 \left[ 1 + \frac{p_1^2}{g_1^0} L_0^4 \left[ M(\theta_m) \left( \cos (\varphi - U) - \cos (\varphi_0 - U) \right) \right] \right],$$

where

$$M = \sqrt{p^2(\theta_m) + \frac{g_2(\theta_m)}{E^2} g_1^0 \frac{g_2^2(\theta_m)}{L^6}}.$$
5–7 Re to the range 5–8 Re, and enable a reasonnable quantitative guess of the processes further out in the magnetosphere. Thus, the usefulness of the Galperin L parameter will be enhanced.

Acknowledgements. This paper resulted from the preparation of a new version of the Maglib software library for the CDPP. We greatly acknowledge D. Boucon for her help in preparing the new version. We would like to thank C. Huc and C. Harvey for their encouragement and support in the updating of the software library. This revised version benefited from the comments of the two referees and precious advice from M. Schulz.

Topical Editor I. A. Daglis thanks S. W. H. Cowley and M. Hapgood for their help in evaluating this paper.
